# Databases

Lecture 9

The Physical Structure of Databases (II)

- Indexes. Tree-Structured Indexing -

#### Indexes - Data Entries

#### **Indexes - Data Entries**

#### Ex. 1

- file with Employee records hashed on age
  - record <lonescu, 60, F, 200>:
    - apply hash function to age: convert 60 to its binary representation, take the 2 least significant bits as the bucket identifier for the record
- index file that uses alternative 1 (data entries are the actual data records), search key age

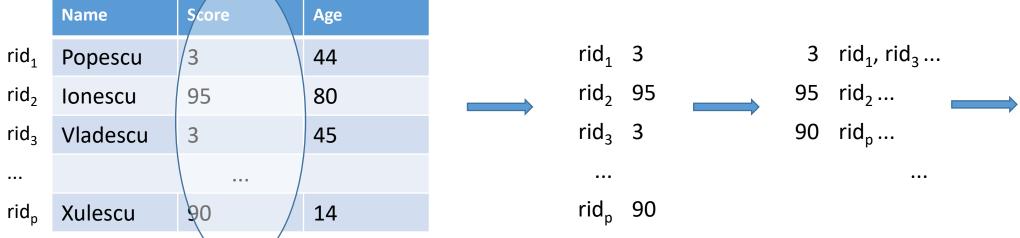

• index that uses alternative 2 (data entries have the form <search key, rid>), search key bonus

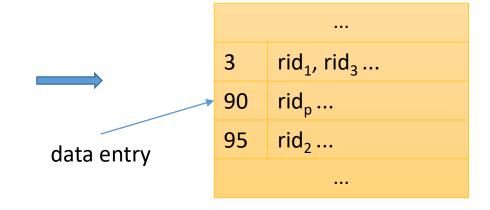

• both indexes use hashing to locate data entries

#### **Indexes - Data Entries**

search key

Ex. 2

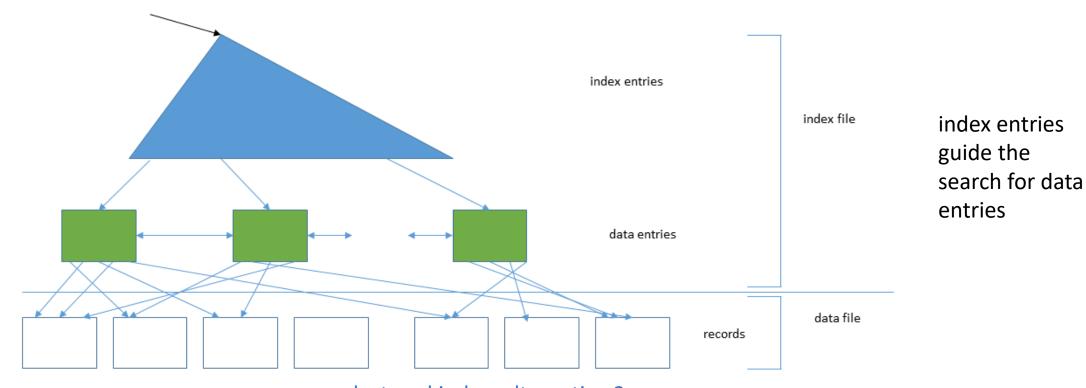

index file

#### Clustered / Unclustered Indexes

- clustered index: the order of the data records is close to / the same as the order of the data entries
- unclustered index: index that is not clustered

#### Clustered / Unclustered Indexes

- index that uses alternative 1 clustered (by definition, since the data entries are the actual data records)
- indexes using alternatives 2 / 3 are clustered only if the data records are ordered on the search key
- in practice:
  - expensive to maintain the sort order for files, so they are rarely kept sorted
  - a clustered index is an index that uses alternative 1 for data entries
  - an index that uses alternative 2 or 3 for data entries is unclustered
- on a collection of records:
  - there can be at most 1 clustered index
  - and several unclustered indexes

#### Clustered / Unclustered Indexes

- range search query (e.g., where age between 20 and 30)
  - cost of using an unclustered index
    - each data entry that meets the condition in the query could contain a rid pointing to a distinct page
    - the number of I/O operations could be equal to the number of data entries that satisfy the query's condition

## Primary / Secondary Indexes

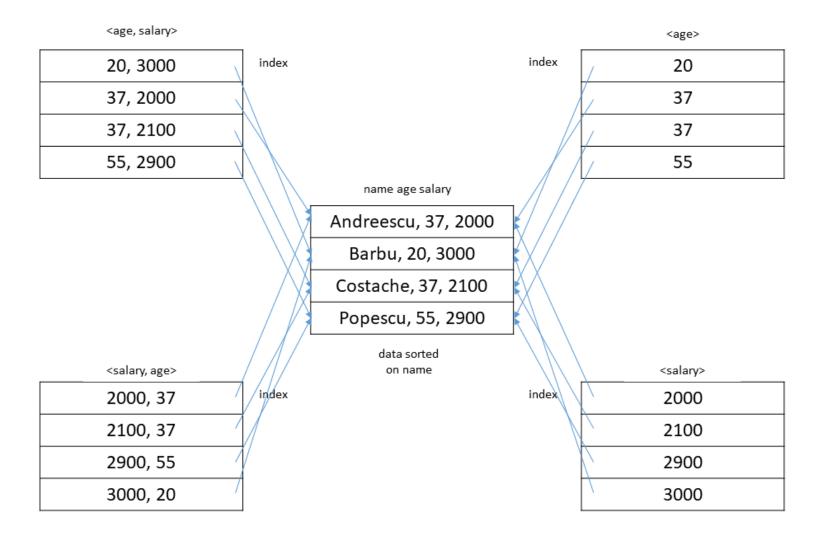

- primary index
  - the search key includes the primary key
- secondary index
  - index that is not primary
- unique index
  - the search key contains a candidate key

- duplicates
  - data entries with the same search key value

- primary indexes, unique indexes cannot contain duplicates
- secondary indexes can contain duplicates

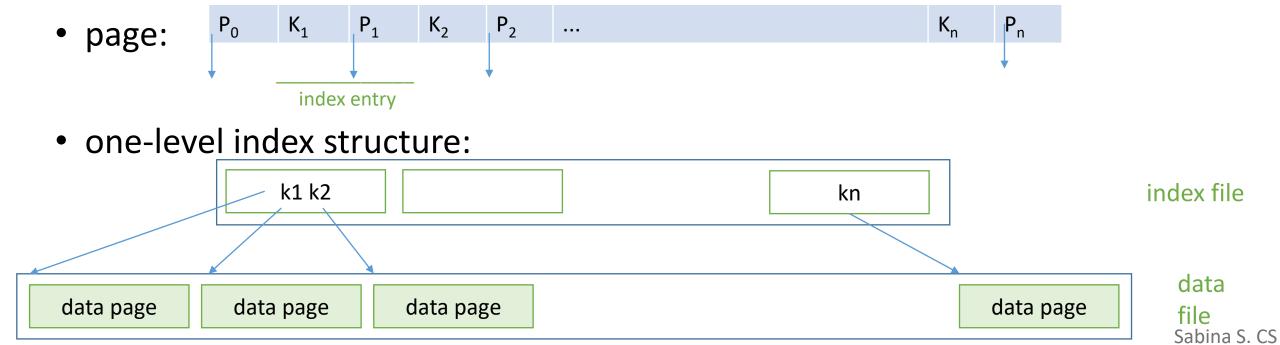

#### Composite Search Keys

- composite (concatenated) search key search key that contains several fields
  - examples

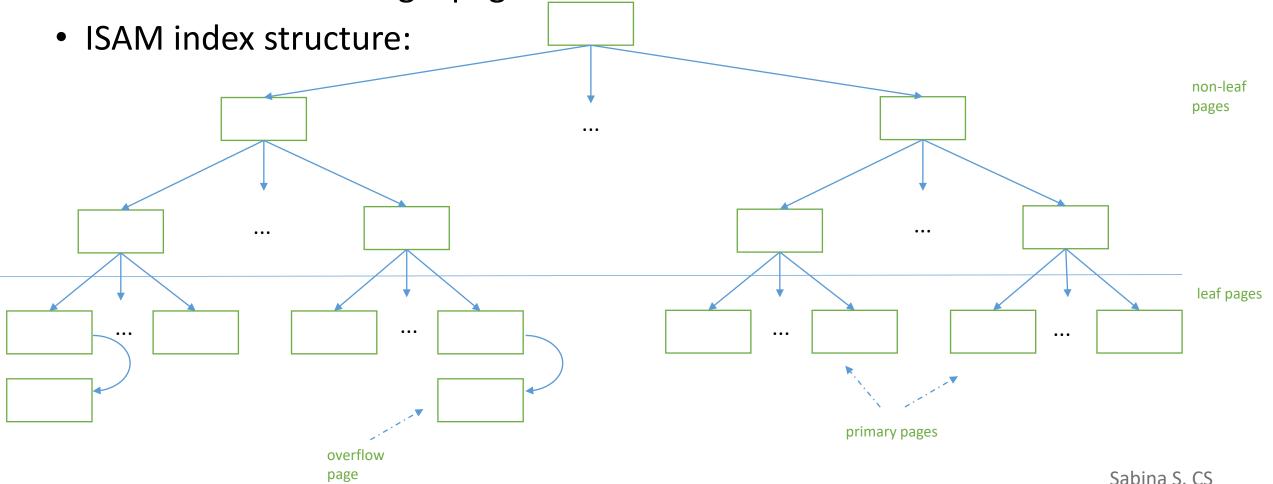

Indexed Sequential Access Method (ISAM)

- \* Example. Q: Find all phones with *rating* > 9 range selection query
- data stored in sorted file (records sorted by *rating*) identify 1<sup>st</sup> phone using binary search; scan file to get the rest of the phones
- large file => potentially expensive binary search
- create another file with records of the form  $<1^{st}$  key on the page, pointer to the page>, sorted on the key (rating in the example)

size of index file - much smaller than size of data file => faster binary search

 index file can still be quite large => further optimization: auxiliary structures are created recursively on top of previously created ones, until one such structure fits on a single page

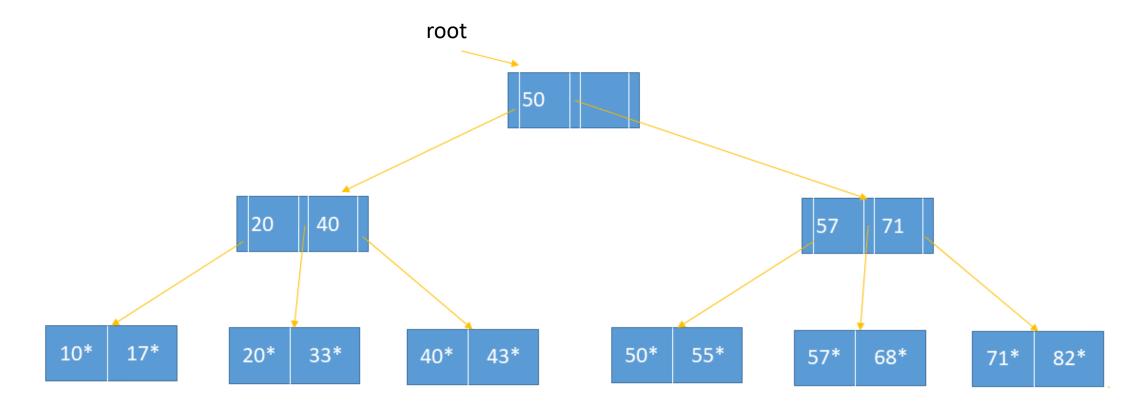

- file creation
  - allocate leaf pages sequentially allocated, sorted on the key

data pages
index pages
overflow pages

- allocate non-leaf pages
- inserts that exceed a page's capacity allocate overflow pages
- search
  - starts at the root
  - comparisons with the key to find the leaf page
  - cost disk I/O

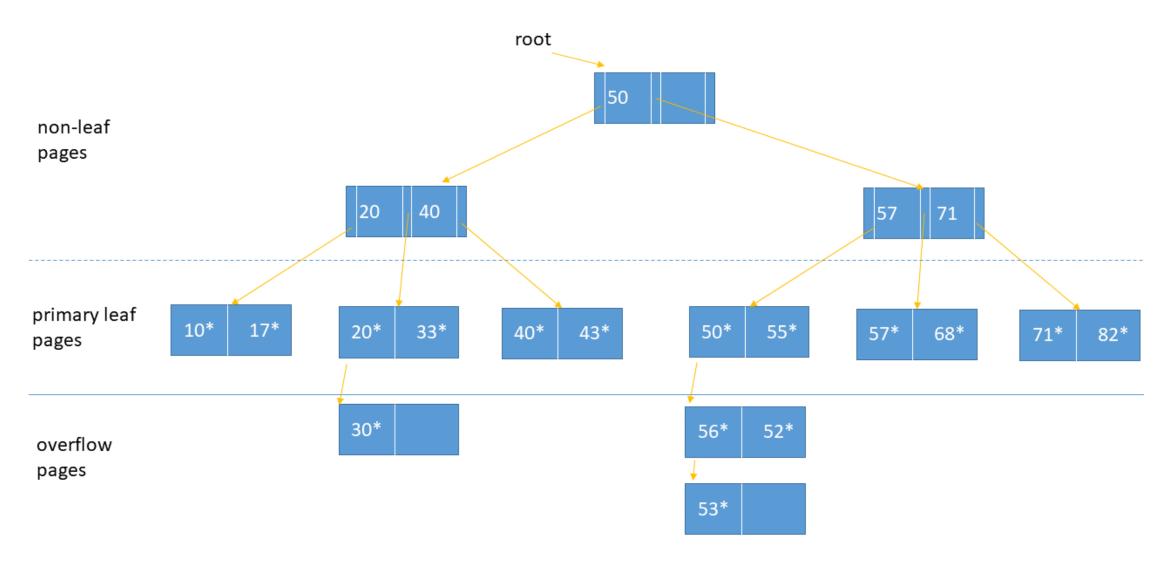

- insertion
  - find the corresponding leaf page, add the entry
  - if there is no space on the page, add an overflow page
- deletion
  - find the leaf page that contains the entry, remove the entry
  - if an overflow page is emptied, it can be eliminated
- inserts / deletes
  - only leaf pages are affected (static structure)

- \* Example ISAM tree
- leaf page 2 entries

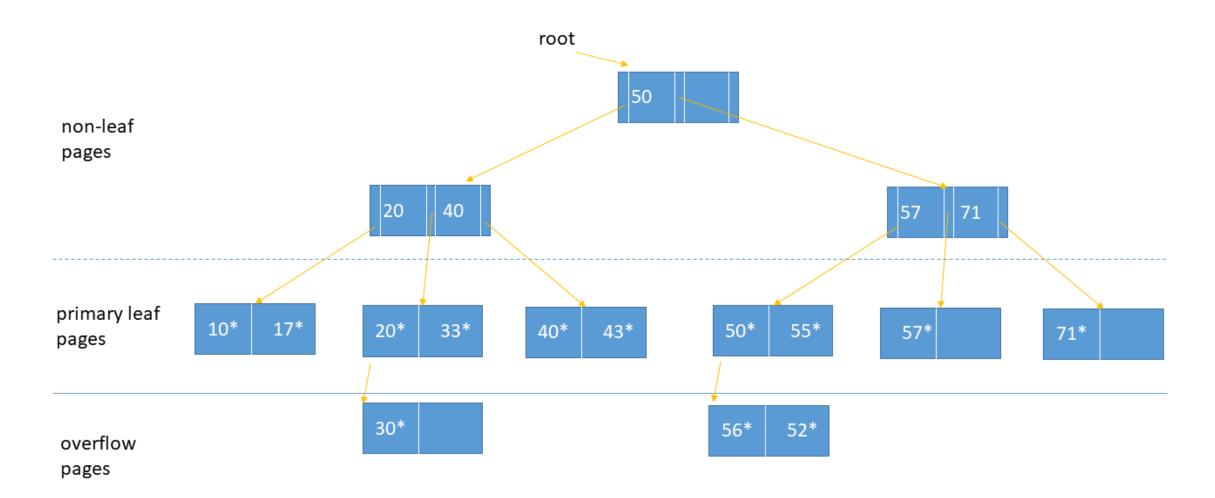

only key values are shown

# • after inserting 30\*, 56\*, 52\*, 53\*

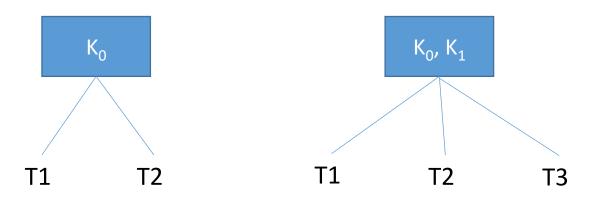

# after deleting 53\*, 68\*, 82\*

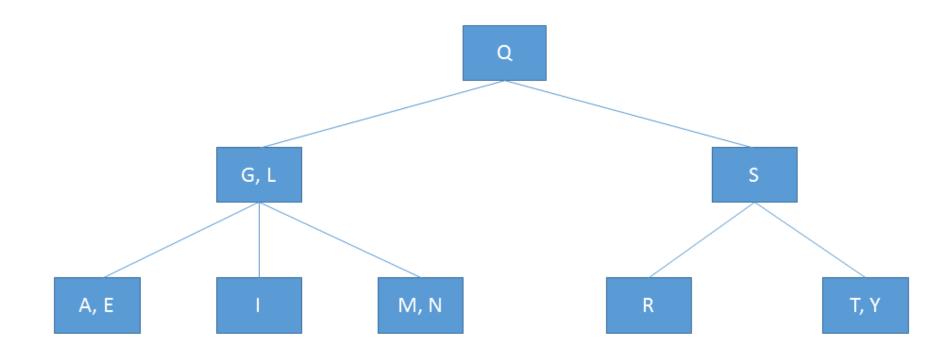

- benefits and drawbacks
  - better concurrent access, since only leaf pages are modified
  - long overflow chains can develop
    - usually not sorted (to optimize inserts)
    - irregular search time if structure not balanced
    - eliminated through deletes / file reorganization
  - when creating the tree 20% of each page free for future inserts
  - ISAM suitable when data size / distribution are relatively static

## 2-3 tree

- 2-3 tree storing key values (collection of distinct values)
- all the terminal nodes are on the same level
- every node has 1 or 2 key values
  - a non-terminal node with one value  $K_0$  has 2 subtrees: one with values less than  $K_0$ , and one with values greater than  $K_0$
  - a non-terminal node with 2 values  $K_0$  and  $K_1$ ,  $K_0 < K_1$ , has 3 subtrees: one with values less than  $K_0$ , a subtree with values between  $K_0$  and  $K_1$ , and a subtree with values greater than  $K_1$

\* Example (key values are letters)

- storing a 2-3 tree
  - 2-3 tree index storing the values of a key
  - tree key value + address of record (file / DB address of record with corresponding key value)

    Sabina S. CS

- 2 options
  - 1. transform 2-3 tree into a binary tree
  - nodes with 2 values are transformed (see figure below)
  - nodes with 1 value unchanged

the structure of a node

K	ADDR	PointerL	PointerR	IND

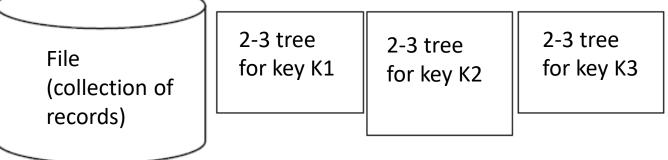

- K key value
- ADDR address of the record with the current key value (address in the file)
- PointerL, PointerR the 2 subtrees' addresses (address in the tree)

- IND indicator that specifies the type of the link to the right (the 2 possible values can be seen in the previous figure)
- 2. the memory area allocated for a node can store 2 values and 3 subtree addresses

NV	K <sub>1</sub>	ADDR <sub>1</sub>	K <sub>2</sub>	ADDR <sub>2</sub>	Pointer <sub>1</sub>	Pointer <sub>2</sub>	Pointer <sub>3</sub>

- NV number of values in the node (1 or 2)
- $K_1$ ,  $K_2$  key values
- ADDR<sub>1</sub>, ADDR<sub>2</sub> the records' addresses (corresponding to K<sub>1</sub> and K<sub>2</sub>)
- Pointer<sub>1</sub>, Pointer<sub>2</sub>, Pointer<sub>3</sub> the 3 subtrees' addresses

• obs. a file (a relation in a relational DB) can have several associated 2-3 trees (one tree / key)

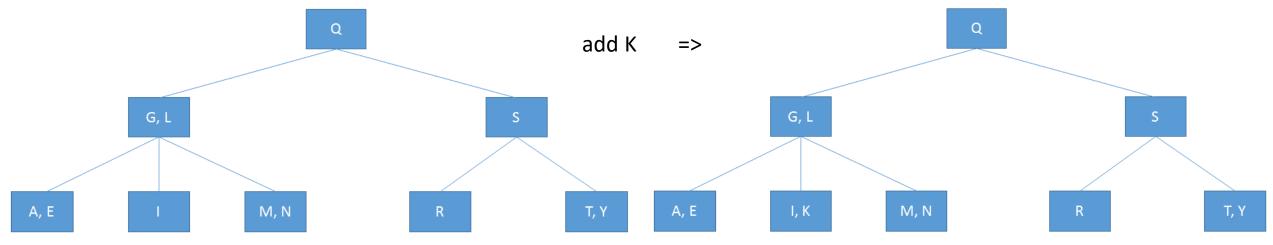

Sabina S. CS

- operations in a 2-3 tree
  - searching for a record with key value K<sub>0</sub>
  - inserting a record description
  - removing a record description
  - tree traversal (partial, total)

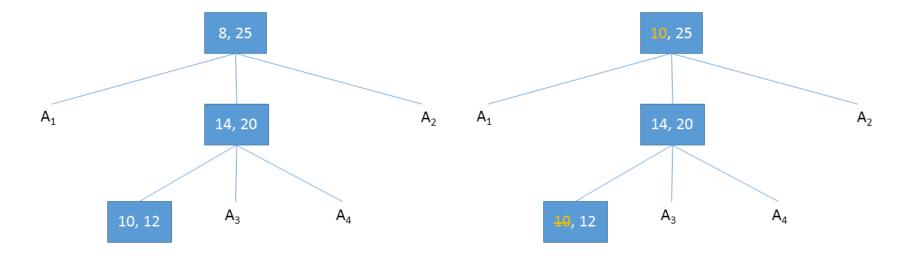

#### add a new value

- values in the tree must be distinct (the new value should not exist in the tree)
- perform a test: search for the value in the tree; if the new value can be added, the search ends in a terminal node
- if the reached terminal node has 1 value, the new value can be stored in the node

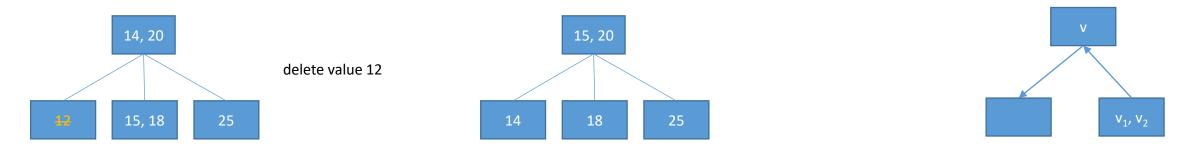

• if the reached terminal node has 2 values, the new value is added to the node, the 3 values are sorted, the node is split into 2 nodes: one node will contain the smallest value, the 2<sup>nd</sup> node - the largest value, and the middle value is attached to the parent node; the parent is then analyzed in a similar manner

- delete a value K<sub>0</sub>
- 1. search for  $K_0$ ; if  $K_0$  appears in an inner node, change it with a neighbor value  $K_1$  from a terminal node (there is no other value between  $K_0$  and  $K_1$ )
  - K<sub>1</sub>'s previous position (in the terminal node) is eliminated
- e.g., remove 8:

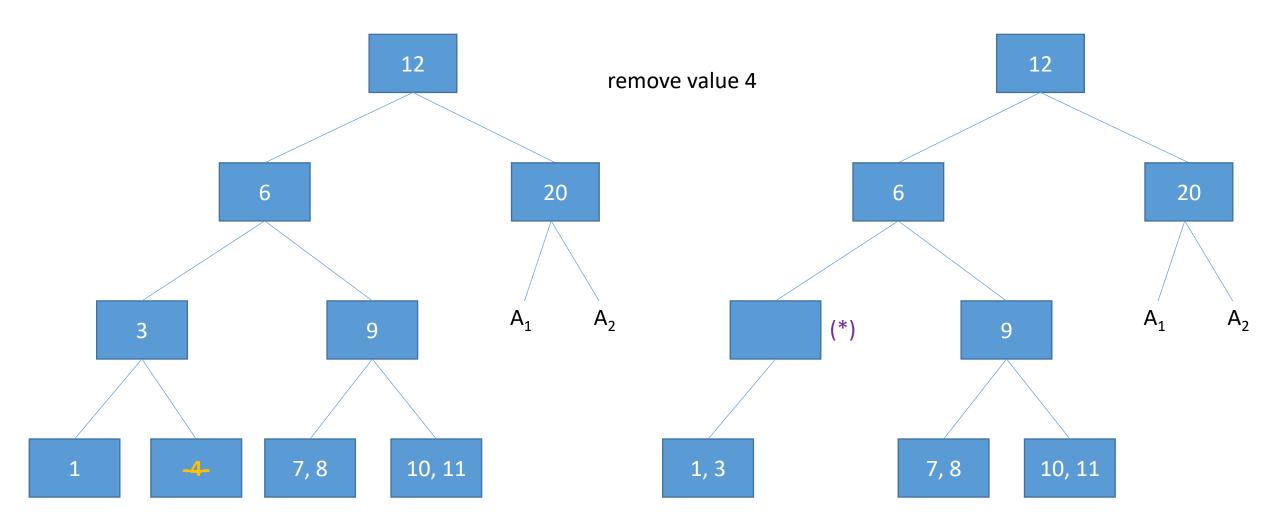

- 2. perform this step until case a / b occurs
- a. if the current node (from which a value is removed) is the root or a node with 1 remaining value, the value is eliminated; the algorithm ends

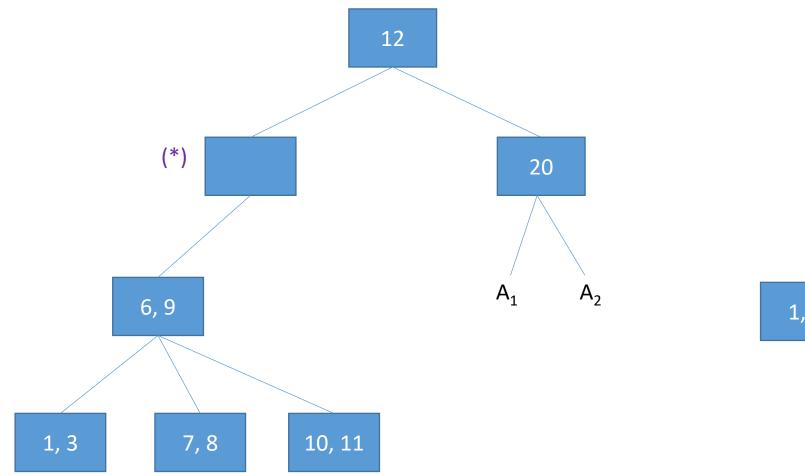

b. if the delete operation empties the current node, but 2 values exist in one of the sibling nodes (left / right), 1 of the sibling's values is transferred to the parent, 1 of the parent's values is transferred to the current node; the algorithm ends

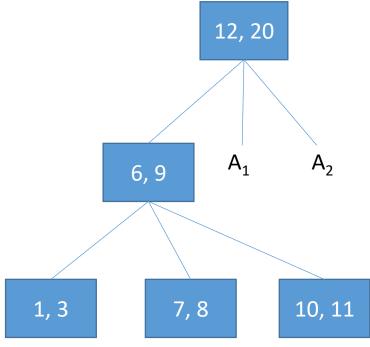

- c. if the previous cases do not occur (current node has no values, sibling nodes have 1 value each), then the current node is merged with a sibling and a value from the parent node; case 2 is then analyzed for the parent
- if the root is reached and it has no values, it is eliminated and the current node becomes the root

# • example: case c for the node marked with (\*)

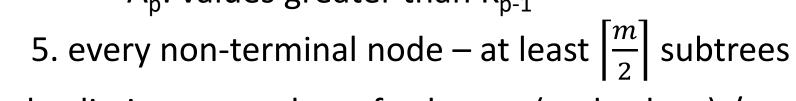

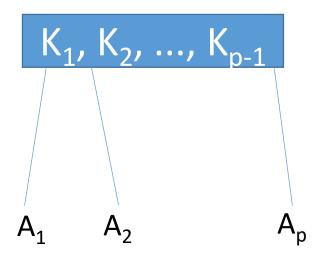

## B-tree

- generalization of 2-3 trees
- B-tree of order m
  - 1. if the root is not a terminal, it has at least 2 subtrees
  - 2. all terminal nodes same level
  - 3. every non-terminal node at most m subtrees
  - 4. a node with p subtrees has p-1 ordered values (ascending order):  $K_1 < K_2 < ... < K_{p-1}$ 
    - A<sub>1</sub>: values less than K<sub>1</sub>
    - A<sub>i</sub>: values between K<sub>i-1</sub> and K<sub>i</sub>, i=2,...,p-1
    - A<sub>p</sub>: values greater than K<sub>p-1</sub>

 obs. limits on number of subtrees (and values) / node result from the manner in which inserts / deletes are performed so that the second requirement in the definition is met \* Example - B-tree of order 5

non-terminal, non-root node – at most 5, at least 3 subtrees (between 2

and 4 values)

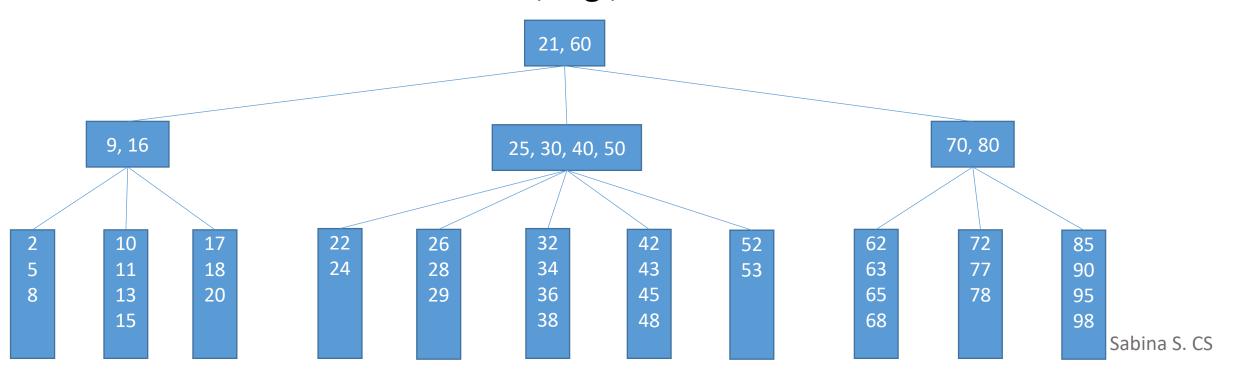

- B-tree of order m
  - storing the values of a key (a database index)
  - tree
    - key value + address of record
  - 1. transformed into a binary tree
    - 2-3 tree method
  - 2. the memory area allocated for a node can store the maximum number of values and subtree addresses

NV K <sub>1</sub> ADDR <sub>1</sub> K <sub>m-1</sub> ADDR <sub>m-1</sub> Pointer <sub>1</sub>	NV	ADDR <sub>1</sub>	K <sub>1</sub>		K <sub>m-1</sub>	ADDR <sub>m-1</sub>	Pointer <sub>1</sub>	•••	Pointer <sub>m</sub>
---	----	-------------------	----------------	--	------------------	---------------------	----------------------	-----	----------------------

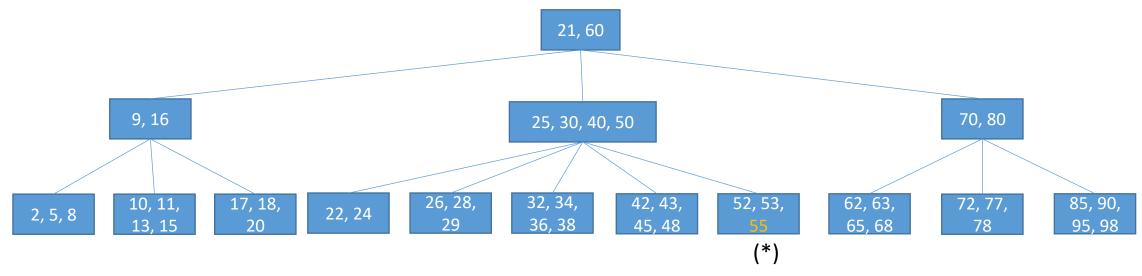

- NV number of values in the node
- K<sub>1</sub>, ..., K<sub>m-1</sub> key values
- ADDR<sub>1</sub>, ..., ADDR<sub>m-1</sub> the records' addresses (corresponding to the key's values)
- Pointer<sub>1</sub>, ..., Pointer<sub>m</sub> subtree addresses

- B-tree of order m
  - useful operations in a B-tree
    - searching for a value
    - adding a value description
    - removing a value- description
    - tree traversal (partial, total)

- B-tree of order m
  - adding a new value
    - 1. values in the tree must be distinct (the new value should not exist in the tree); perform a test (search for the value in the tree)
    - if the new value can be added, the search ends in a terminal node
    - 2. if the reached terminal node has less than m-1 values, the new value can be stored in the node, e.g., 55 is added to the tree below:

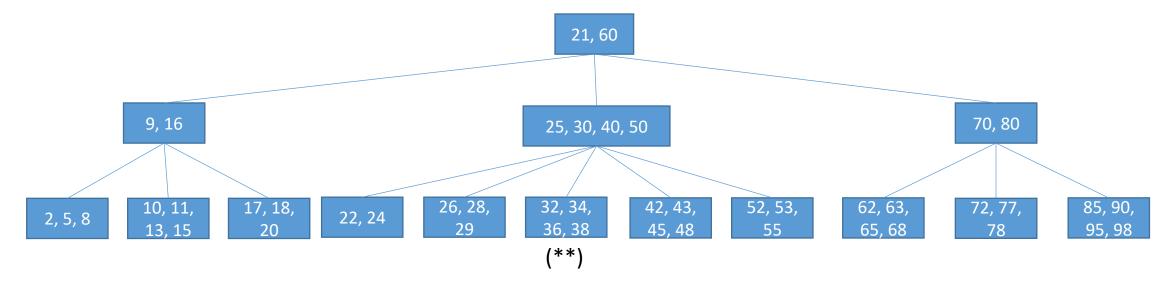

- B-tree of order m
  - adding a new value
    - the resulting tree is shown below:

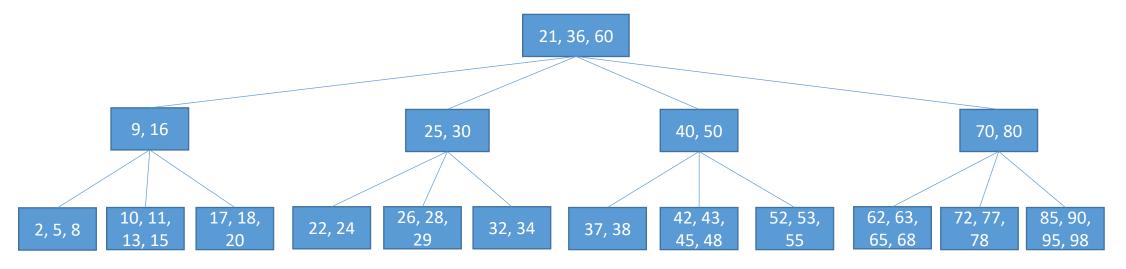

• 55 belongs to the node marked with (\*), which can store at most 4 values

- B-tree of order m
  - adding a new value
    - 3. if the terminal node already has m-1 values, the new value is attached to the node, the m values are sorted, the node is split into 2 nodes, and the middle value (median) is attached to the parent node; the parent is then analyzed in a similar manner
      - e.g., add 37 to the tree below

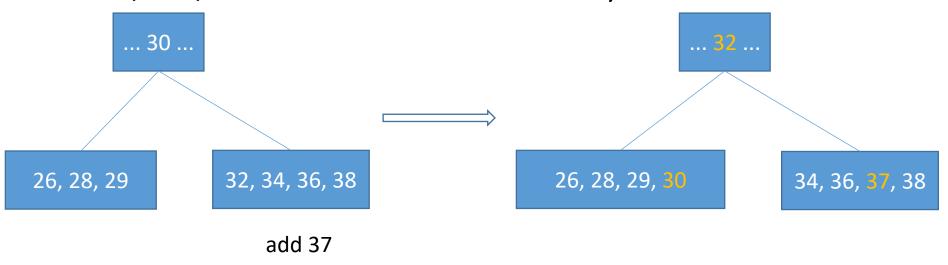

• the node marked with (\*\*) should contain values 32, 34, 36, 37, 38

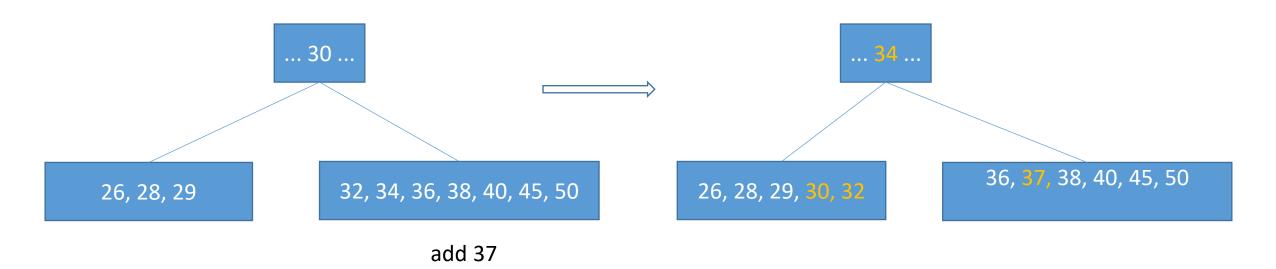

- B-tree of order m
  - adding a new value
    - since the node's capacity is exceeded, it is split into nodes 32, 34, and 37, 38, and 36 is attached to the parent node (with values 25, 30, 40, 50)
    - in turn, the parent must be split into 2 nodes (values 25, 30, and 40, 50), and 36 is attached to its parent

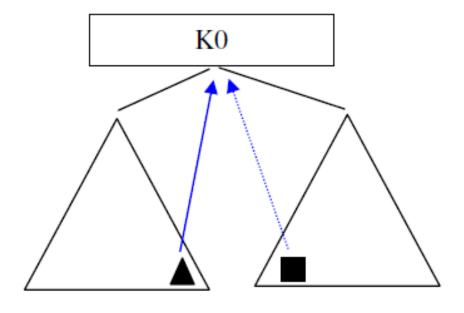

- B-tree of order m
  - adding a new value
    - optimizations
      - before performing a split analyze whether one or more values can be transferred from the current node (with m-1 values) to a sibling node
      - e.g., B-tree of order 5 (non-terminal node between 2 and 4 values, i.e., between 3 and 5 subtrees):

- B-tree of order m
  - adding a new value
    - optimizations
    - e.g., B-tree of order 8 (non-terminal node between 3 and 7 values, i.e., between 4 and 8 subtrees):

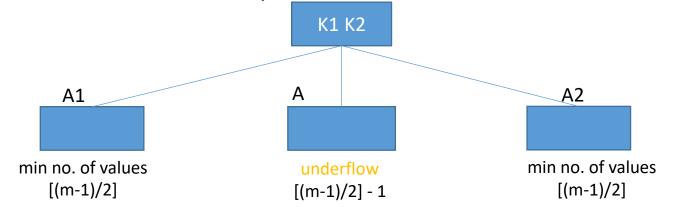

- B-tree of order m
  - removing a value
    - a node can have at most m subtrees, i.e., a maximum of m-1 values, and at least  $\left\lceil \frac{m}{2} \right\rceil$  subtrees, i.e., at least  $\left\lceil \frac{m}{2} \right\rceil 1 = \left\lceil \frac{m-1}{2} \right\rceil$  values
    - when eliminating a value from a node, an underflow can occur (the node can end up with less values than the required minimum)
  - eliminate value K<sub>0</sub>
    - 1. search for  $K_0$ ; if it doesn't exist, the algorithm ends
    - 2. if  $K_0$  is found in a non-terminal node (like in the figure on the right),  $K_0$  is replaced with a *neighbor value* from a terminal node (this value can be chosen between 2 values from the trees separated by  $K_0$ )

- B-tree of order m
  - removing a value
    - 3. perform this step until case a / b occurs
    - a. if the current node (from which a value is removed) is the root or underflow doesn't occur, the value is eliminated; the algorithm ends
    - b. if the delete operation causes an underflow in the current node (A), but one of the sibling nodes (left / right B) has at least 1 extra value, values are transferred between A and B via the parent node; the algorithm ends
    - c. if there is an underflow in A, and sibling nodes A1 and A2 have the minimum number of values, nodes must be concatenated:

Sabina S. CS

- B-tree of order m
  - removing a value
    - if A1 exists, A1 is merged with A and value K1 (separating A1 from A); the node at address A1 is deallocated

A
Elem(A1), K1, Elem(A)

• if there is no A1 (A is the first subtree for its parent), A is merged with A2 and K1 (separating A from A2); the node at address A2 is deallocated

A
Elem(A), K1, Elem(A2)

- case 3 is then analyzed for the parent node
- if the root is reached and has no values, it is removed and the current node becomes the root

- B-tree of order m
  - obs. a block stores a node from a B-tree
- e.g.:
  - key size: 10b
  - record address / node address: 10b
  - NV value (number of values in the node): 2b
  - block size: 1024b (10b for the header)
- then: 2+(m-1)\*(10+10)+m\*10=1024-10 => m=34
- if the size of a block is 2048b and the other values are unchanged, then the order of the tree is m = 68, i.e., a node can have between 33 and 67 values

- B-tree of order m
- the maximum number of required blocks (from the file that stores the B-tree) when searching for a value the maximum number of levels in the tree; for m=68, if the number of values is 1.000.000, then:
  - the root node (on level 0) contains at least 1 value (2 subtrees)
  - on the next level (level 1) at least 2 nodes \* 33 values/node = 66 values
  - level 2 at least 2\*34 nodes \* 33 values/node = 2.244 values
  - level 3 at least 2\*34\*34 nodes \* 33 values/node = 76.296 values
  - level 4 at least 2\*34\*34\*34 nodes \* 33 values/node = 2.594.064 values, which is greater than the number of existing values => this level does not appear in the tree
- => at most 4 levels in the tree
- after at most 4 block reads and a number of comparisons in main memory, it can be determined whether the value exists (the corresponding record's address can then be retrieved) or the search was unsuccessful
